# Control Review

## 1DOF Feedback Interconnection

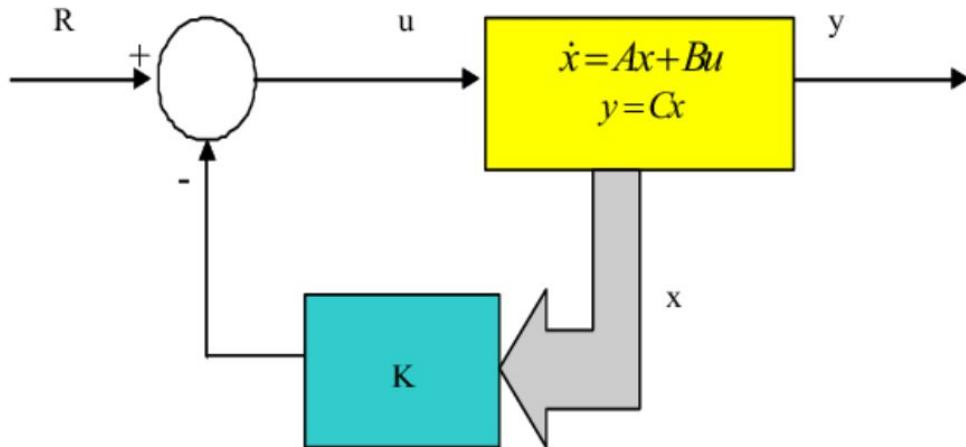

- ▶  $r(s)$ : command (a.k.a. reference).
- ▶  $n(s)$ : measurement noise.
- ▶  $d(s)$ : disturbance.
- ▶  $P(s)$  or  $z(s) = P(s)v(s)$ : plant TF (a.k.a. process TF).
  - ▶  $z(s)$ : plant output.
  - ▶  $v(s) = d(s) + u(s)$ : plant input.
- ▶  $C(s)$  or  $u(s) = C(s)e(s)$ : controller (a.k.a. compensator) to be designed.
  - ▶  $u(s)$ : controller output.
  - ▶  $e(s) = r(s) - y(s) = r(s) - z(s) - n(s)$ : control input.
  - ▶  $y(s)$ : measurement.

# Satellite Model

State column matrix ( $x$ ) : position, velocity, angular rate, etc.

Actuator column matrix ( $u$ ): magnetorquer

# LQR Specific Overview

- Yellow block is our satellite model
- LQR is the  $K$  matrix
- $K$  is removed from reference  $R$  and fed back to model

# LQR Optimization

Posing the Control problem as an optimization problem to find where to place our poles (OLHP). In control theory, we are always trading-off between performance and robustness. We therefore set up a cost function to weight each of these criterias.

$$J = \int_{0}^{\infty} (x^T Q x + u^T R u) dt$$

penalize bad performance      penalize actuator effort

x is the state vector (what we are measuring), ex: angular position, velocity

Q is nxn to match dimension of state. Positive-semidefinite matrix

R matches dimension of input. Positive definite matrix. If we have one input (ex: 1 thruster), R is a scalar.

# LQR Optimization

R and Q weighted matrices are diagonal matrices.

R will penalize high efforts in the magnetorquer which will use up a lot of the battery. (Larger R means the satellite will smoothly slew to its desired position and therefore be more energy efficient)

Q will penalize large amounts of time spent NOT at our reference. (Larger Q means the satellite will move more aggressively to get to desired position)

$$\begin{bmatrix} Q_1 & 0 & 0 & \dots & 0 \\ 0 & Q_2 & 0 & \dots & 0 \\ 0 & 0 & Q_3 & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & Q_n \end{bmatrix}$$

$$\begin{bmatrix} R_1 & 0 & 0 & \dots & 0 \\ 0 & R_2 & 0 & \dots & 0 \\ 0 & 0 & R_3 & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & R_n \end{bmatrix}$$

The difference between Q1, Q2, etc is based on which state they are mapped to.

Example: I want to prioritize accuracy of the angular position of my spacecraft over any other state. If we chose angular position to be x1 and z position to be x2, I should choose Q1 to be larger than Q2,Q3,etc in order to penalize errors in angular position heavily

\*\*R and Q are not necessarily the same dimension

# Expanded Representation Cost Function

$$[x_1, x_2, \dots, x_n] \begin{bmatrix} Q_1 & & O \\ & Q_2 & \\ O & & \ddots & \\ & & & Q_n \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix} \quad [u_1, u_2, \dots, u_m] \begin{bmatrix} R_1 & & O \\ & R_2 & \\ O & & \ddots & \\ & & & R_m \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ \vdots \\ u_m \end{bmatrix}$$

Q1: How much does it cost to have errors in my state  $x_1$

R1: How much does it cost to use and actuate the controller  $u_1$

# Implementation - MATLAB

- 1) Once we have a linearized model of our satellite in the form:

$$\begin{aligned}\dot{x} &= Ax + Bu \\ y &= Cx + Du\end{aligned}$$

- 2) We can adjust the diagonal terms of Q and R based on our design decisions. A good starting point is Identity for both matrices.
- 3) In MATLAB, use the function  $k=lqr(A, B, Q, R)$  to find the optimal gains.
- 4) Simulate the system with  $\text{sys} = \text{ss}(A - B^*K, B, C, D)$
- 5) if changes need to be done, adjust Q and R and rerun sims.
